We report measurements of target- and double-spin asymmetries for the exclusive channel $\vec{e}\vec{p} \rightarrow e\pi^+ (n)$ in the nucleon resonance region at Jefferson Lab using the CEBAF Large Acceptance Spectrometer (CLAS). These asymmetries were extracted from data obtained using a longitudinally polarized NH$_3$ target and a longitudinally polarized electron beam with energies 1.1, 1.3, 2.0, 2.3, and 3.0 GeV. The new results are consistent with previous CLAS publications but are extended to a low $Q^2$ range from 0.0065 to 0.35 (GeV/$c$)$^2$. The $Q^2$ access was made possible by a custom-built Cherenkov detector that allowed the detection of electrons for scattering angles as low as 6°. These results are compared with the unitary isobar models JANR and MAID, the partial-wave analysis prediction from SAID, and the dynamic model DMT. In many kinematic regions our results, in particular results on the target asymmetry, help to constrain the polarization-dependent components of these models.

DOI: 10.1103/PhysRevC.94.045206

I. PHYSICS MOTIVATION

The perturbative nature of the strong interaction at small distances—often referred to as “asymptotic freedom”—was established more than 30 years ago and provided strong support for quantum chromodynamics (QCD) to be accepted as the correct theory for strong interactions [1,2]. On the other hand, calculations at long distances are still beyond reach because of the nonperturbative nature at this scale. As a result, we are still far away from being able to describe the strong force as it manifests itself in the structure of baryons and mesons [3,4]. A fundamental approach to resolve this difficulty is to develop a low $Q^2$ range from 0.0065 to 0.35 (GeV/$c$)$^2$. The $Q^2$ access was made possible by a custom-built Cherenkov detector that allowed the detection of electrons for scattering angles as low as 6°. I. PHYSICS MOTIVATION

The perturbative nature of the strong interaction at small distances—often referred to as “asymptotic freedom”—was established more than 30 years ago and provided strong support for quantum chromodynamics (QCD) to be accepted as the correct theory for strong interactions [1,2]. On the other hand, calculations at long distances are still beyond reach because of the nonperturbative nature at this scale. As a result, we are still far away from being able to describe the strong force as it manifests itself in the structure of baryons and mesons [3,4]. A fundamental approach to resolve this difficulty is to develop accurate numerical simulations of QCD on the lattice; for recent reviews see [5,6]. However lattice QCD methods are difficult to apply to light-quark systems such as the nucleon. Alternatively, hadron models with effective degrees of freedom have been constructed to interpret data. One example is the chiral perturbation theory [7,8], which is constrained only by the symmetry properties of QCD. The constituent quark model, though not fully understood, is one successful example that works almost everywhere from hadron spectroscopy to deep inelastic scattering [9,10]. Predictions for the scattering amplitudes and polarization-dependent asymmetries exist for many resonances within the framework of the relativistic constituent quark model (RCQM) [11] and the single quark transition model (SQTM) [12].

The comparison between these predictions and experimental results, on the other hand, is not straightforward. This is because the experimentally measured cross sections and asymmetries are usually complicated combinations of resonant and nonresonant amplitudes and couplings, and their interference terms. To compare with theories, partial wave analyses are often used to extract these amplitudes and resonance couplings from data. Once comparisons can be made, data are used to provide inputs for constructing or adjusting meson production mechanisms in theories and models, such as proper treatment of the hadronic final state and implementation of the nonresonant part of the meson production amplitude. These mechanisms are usually not included in quark models. Examples of phenomenological partial wave analyses that can benefit from more data are MAID [13], JANR [14], SAID [15], and the DMT [16] models. Electron-scattering data used to test these calculations include primarily $N \rightarrow N^*$ transition form factors and response functions for meson production reactions obtained from Jefferson Lab (JLab), MAMI, and MIT-Bates. Recently, polarization observables such as double-spin asymmetries and target spin asymmetries for pion electroproduction from the proton have made the beam- and target-helicity response functions accessible [17–20], providing a new approach to testing models and to a greater understanding of the baryon resonance structure. As an example, the MAID model was based mostly on unpolarized data and is only recently being tested extensively against double polarization asymmetries. In general, polarization observables provide an important constraint on the understanding of the underlying helicity response functions or interference terms in $N \rightarrow \Delta$ and $N \rightarrow N^*$ resonances.

Compared to the proton, existing data on neutron excitation were particularly sparse. Neutron data have recently become available from JLab [21,22], which make it possible to test the isospin structure of models such as RCQM and SQTM. The neutron data will be valuable to the development of many phenomenological analyses as well because they need to incorporate double polarization asymmetry data for all pion production channels from both the proton and the neutron to perform the full isospin decomposition.

In addition, data at very low $Q^2$ values are often desired for testing the chiral perturbation theory and to study the transition
AN double-spin asymmetry is dominated by the frozen spin target with a longitudinal polarization and a resonance must cross zero at some intermediate \( Q \) with \( Q^2 \) being available from the CBELSA/TAPS Collaboration [25]. This indicates that \( A^N \) for four-momentum \( q \equiv (v, \hat{q}) \) to the target nucleon \( N \) which forms a nucleon resonance. The resonance then decays into a pion and another particle \( X \). Two planes are used to describe this process: the scattering (leptonic) plane defined by the incoming and outgoing electrons’ momenta \( \vec{k} \) and \( \vec{k}' \), and the reaction (hadronic) plane defined by the momentum of the virtual photon \( \hat{q} \) and the momentum of the outgoing pion \( \vec{p}_\pi \).

The reaction is usually described in terms of \( Q^2 \), the invariant mass \( W \) of the \( \gamma^*N \) system (which is also the \( \pi X \) system), and two angles \( \theta^* \) and \( \phi^* \). Here, \( \theta^* \) is the angle formed by \( \hat{q} \) and \( \vec{p}_\pi \), and \( \phi^* \) is the angle formed by rotating the leptonic plane to the hadronic plane. If one defines the \( \gamma^*N \) center-of-mass (CM) frame with \( \hat{z} \) pointing along \( \hat{q} \) and \( \hat{y} \) along \( \hat{q} \times \hat{k} \), then \( \theta^* \) and \( \phi^* \) are the polar and the azimuthal angles of the emitted pion. The energy transfer is related to \( Q^2 \) and \( W \) via

\[
v = \frac{W^2 + Q^2 - M^2}{2M},
\]

with \( M \) the nucleon mass. The differential cross section for the reaction \( e\bar{N} \rightarrow e\pi(X) \) with longitudinally polarized beam and target can be written in the following form:

\[
\frac{d^3\sigma_b}{dE_e d\Omega_e^* d\Omega_\pi^*} = \frac{\Gamma}{d\Omega_\pi^*},
\]

with

\[
\frac{d\sigma_{et}}{d\Omega_\pi^*} = \frac{d\sigma_b}{d\Omega_\pi^*} + P_b \frac{d\sigma_{e}}{d\Omega_\pi^*} + P_i \frac{d\sigma_{t}}{d\Omega_\pi^*} + P_b P_i \frac{d\sigma_{et}}{d\Omega_\pi^*},
\]

where \( P_b \) and \( P_i \) are, respectively, the polarizations of the electron beam and the target along the beam direction, \( \sigma_b \) is the unpolarized cross section, and \( \sigma_e, \sigma_t, \) and \( \sigma_{et} \) are the polarized cross-section terms when beam, target, and both beam and target are polarized. Note that the differential cross sections on the right-hand side of Eq. (5) are defined in the CM frame of the \( \gamma^*N \) system, as indicated by the asterisk in the pion’s solid angle. The virtual photon flux is

\[
\Gamma = \frac{\alpha k_{\gamma}^{lab}}{2\pi Q^2} E' \frac{1}{E(1-\epsilon)},
\]

where \( \alpha \) is the electromagnetic coupling constant, \( k_{\gamma}^{lab} = (W^2 - M^2)/2M \) is the photon equivalent energy in the laboratory frame, i.e., the energy needed by a real photon to excite the nucleon to an invariant mass \( W \). The virtual photon polarization is given by

\[
\epsilon = \left[ 1 + \frac{2|\vec{q}|^2}{Q^2} \tan^2 \frac{\theta_e}{2} \right]^{-1},
\]

where \( \theta_e \) is the angle between the incident and outgoing electrons in the laboratory frame. The \( Q^2 \) can be calculated as

\[
Q^2 = 4E E' \sin^2 \frac{\theta_e}{2}.
\]

To evaluate the pion’s kinematics in the CM frame of the \( \gamma^*N \) system, we relate a laboratory-frame 4-momentum vector \( p^\mu \) to the CM frame \( p_{cm}^\mu \) via a Lorentz boost with \( \beta = \vec{z}/|\vec{q}|/(\nu + M) \) and \( \gamma = (\nu + M)/W \):

\[
p_{cm}^\mu = \gamma p^\mu - \gamma \beta p^\gamma,
\]
\[ p'_{cm} = p^x, \]  
\[ p_{cm} = p^y, \]  
\[ p''_{cm} = -\gamma \beta p^0 + \gamma p^z. \]  
Specifically, we have for the virtual photon:

\[ |\bar{q}_{cm}| = \frac{M}{W} |\bar{q}|, \]  
\[ v_{cm} = \frac{\nu M - Q^2}{W}. \]

For the pion,

\[ E_{cm,\pi} = \gamma (E_\pi - \beta |\vec{p}_\pi| \cos \theta_\pi), \]  
\[ \rho_{z,cm,\pi} = \gamma |\vec{p}_\pi| \cos \theta_\pi - \beta E_\pi, \]

where \( \theta_\pi = \arccos (|\bar{q} \cdot \vec{p}_\pi| / (|\bar{q}| |\vec{p}_\pi|)) \) is the angle between the pion momentum and \( \bar{q} \) in the laboratory frame, and \( E_\pi \) is the pion energy again in the laboratory frame. The polar angle of the pion in the CM frame is given by

\[ \theta^* = \arccos \left( \frac{\rho_{z,cm,\pi}}{E_{cm,\pi} - m_\pi^2} \right), \]

where \( m_\pi \) is the pion mass. The azimuthal angle of the pion is the same in the laboratory and the CM frame, given by

\[ \phi^* = \arccos \left( \frac{\bar{a} \cdot \bar{b}}{|\bar{a}| |\bar{b}|} \right). \]

with \( \bar{a} \equiv \bar{q} \times \vec{k} \) and \( \bar{b} \equiv \bar{q} \times \vec{p}_\pi \). In this paper, the range of \( \phi^* \) is defined from 0 to \( 2\pi \), i.e., a shift of \( 2\pi \) is added to \( \phi^* \) if the result from Eq. (18) is negative.

The beam, target, and double beam-target asymmetries are

\[ A_{LU} = \frac{\sigma_{UL}}{\sigma_0}, \]  
\[ A_{UL} = \frac{\sigma_{UL}}{\sigma_0}, \]  
\[ A_{LL} = -\frac{\sigma_{LL}}{\sigma_0}, \]

where each cross section \( \sigma \) stands for the \( d\sigma /dQ^2 \) of Eq. (5). Note that we have adopted an extra minus sign in the definition of \( A_{LL} \) to be consistent with Eq. (2) and previous CLAS publications [17–19].

In this paper, we report on results of both \( A_{UL} \) and \( A_{LL} \) extracted from the JLab CLAS EG4 [29,30] data. The beam asymmetry \( A_{LU} \) was also extracted from the data, but was used only as a cross check of the beam helicity and is not presented here. These results are available for download from the CLAS database.

### B. Previous data

The first double-spin asymmetry for the \( \pi^+ n \) channel was published based on the CLAS EG1a data with a 2.6-GeV beam, for a \( Q^2 \) range from 0.35 to 1.5 (GeV/c)^2 [17,18]. The \( \bar{e} \bar{p} \rightarrow e' p (\pi^0) \) channel was analyzed for the \( \Delta(1232)3/2^+ \) region using the same data set [19]. Similar analysis using the CLAS EG1b data was completed [20,22], in which the target and the double-spin asymmetries were extracted from both the \( \bar{e} \bar{p} \rightarrow e'\pi^+ (n) \) and \( \bar{e} \bar{n} \rightarrow e'\pi^- p \) channels using 1.6–5.7 GeV beams with \( Q^2 \) as low as 0.1 (GeV/c)^2.

### II. THE JLAB CLAS EG4 EXPERIMENT

The main physics goal of the CLAS EG4 experiment [29,30] was to measure the inclusive spin structure functions on the proton and the deuteron, and to extract the generalized Gerasimov-Drell-Hearn (GDH) sum near the photon point. The original GDH sum rule [31,32], defined for real photons, is a fundamental prediction on the nucleon’s spin structure that relates the helicity-dependent total photoabsorption cross section to the nucleon anomalous magnetic moment. The definition of the GDH sum was generalized to virtual photons [33,34], and the value of the generalized GDH sum at low \( Q^2 \) was predicted in the chiral perturbation theory. Similar to the pion production results presented here, the goal of the EG4’s inclusive analysis is to test the chiral perturbation theory prediction and to compare the extrapolation to the \( Q^2 = 0 \) point with the GDH sum rule of the real photon.

The experiment was carried out in 2006 in experimental Hall B of JLab. Inclusive data were collected in the range \( 1 < W < 2 \) GeV/c^2 and \( Q^2 \) down to 0.015 (GeV/c)^2 [35], using six beam energies (1.1, 1.3, 1.5, 2.0, 2.3, 3.0 GeV) on a polarized NH3 target and two energies (1.3, 2.0 GeV) on a polarized ND3 target. The average polarizations of NH3 and ND3 typically ranged within 75%-90% and 30%-45%, respectively. For the exclusive channel, only NH3 data with beam energies of 1.1, 1.3, 2.0, 2.3, and 3.0 GeV were analyzed with the lowest \( Q^2 \) being 0.0065 (GeV/c)^2. The 1.5-GeV energy data were excluded because they were taken for run commissioning purposes and had limited statistics. For ND3 data, the target spin direction was not flipped during the run, which makes it impossible to extract \( A_{UL} \) or the complete information on \( A_{LL} \) from the exclusive channel.

#### A. The CLAS detector

The CEBAF Large Acceptance Spectrometer (CLAS) was used to detect scattered particles [36]. Figure 2 shows the basic structure of CLAS during EG4 with the polarized target installed. CLAS is an almost hermetic detector, optimized for the measurement of multiparticle final states in a large momentum region. The detector design is based on a toroidal magnet made by six superconducting coils arranged around the beam line to produce a field pointing primarily in the azimuthal direction. The field direction can be set such that the scattered negatively charged particles can be either bent away from the beamline ("electron outbending") or towards it ("electron inbending"). The detector itself is composed of six independent magnetic spectrometers, referred to as six "sectors," with a common target, trigger, and data acquisition system. Each sector is equipped with a three-layer drift chamber (DC) system for momentum and tracking determination, a time-of-flight (TOF) counter, a Cherenkov counter (CC), and a double-layer electromagnetic calorimeter (EC). The TOF, CC, and EC systems are primarily used for determining the particle type.
To reach very low $Q^2$ while retaining the high beam energy needed to measure the GDH sum, a small scattering angle was necessary. This was achieved by running the CLAS torus magnet in the electron-outbending configuration. Although the standard CLAS Cherenkov detector geometrically reaches an $8^\circ$ scattering angle [37], its structure is not ideal for collecting the Cherenkov light for outbending electrons. Therefore, for the EG4 experiment, a new Cherenkov detector was built by the INFN-Genova group and installed in sector 6, as shown in Fig. 2. It was designed to reach $6^\circ$ scattering angle by optimizing the light collection for the electron-outbending configuration. Because of the very high counting rates at such low scattering angles, instrumenting only one CLAS sector was sufficient for the experiment. The new Cherenkov detector used the same radiator gas (C$_4$F$_{10}$) and the gas flow control system used in the standard CLAS Cherenkov. It consisted of 11 segments, each equipped with a pair of light-weight spherical mirrors; see Fig. 3. The mirrors were constructed following [38], by shaping a plexiglass layer onto a spherical mould, then gluing onto it a sandwich of carbon fiber and honeycomb, and finally evaporating a thin layer of aluminum onto the plexiglass. Each mirror reflected the light towards a light collector made of two pieces, an entrance section with the approximate shape of a truncated pyramid and a guiding section cylindrical in shape such as to match the circular photocathode. Each light collector was made of plexiglass with aluminum evaporated on the internal surface. The entrance section was built by a no-contact technique, where the plexiglass sheet was heated and pushed against a mould with the desired shape, then the bottom of the obtained object was cut to permit the free passage of light. The cylindrical section was obtained by cutting a plexiglass tube. The two sections were then glued together before evaporating the reflective layer. For the PMTs, the Photonis XP4508B with quartz window were chosen. The photoelectron yield was greater than $\approx 10$ within the kinematic region of the experiment, thereby yielding a high electron detection efficiency down to a scattering angle of about $6^\circ$. Signals from the new Cherenkov were built into the main electron trigger during EG4. Consequently only $1/6$ of the full azimuthal acceptance of CLAS was used to detect and identify forward-angle scattered electrons.

### B. The polarized electron beam

The polarized electron beam was produced by illuminating a strained GaAs photocathode with circularly polarized light. The helicity of the electron beam was selected from a pseudorandom sequence, and followed a quartet structure of either “$+ - + -$” or “$- + + -$”, with each helicity state lasting 33 ms. The helicity sequence controlled the trigger system, and periods of beam instability from helicity reversal were rejected from the data stream. To reduce possible systematic uncertainties, data were taken for two different beam helicity configurations, with the beam insertable half-wave plate (HWP) inserted (in) and removed (out), respectively. The polarization of the electron beam was measured by both a Möller and a Mott polarimeter.

### C. The polarized targets

The polarized targets used for EG4 were the frozen $^{15}$NH$_3$ and $^{14}$ND$_3$ targets dynamically polarized at 1 K with a 5-Tesla field. These were the same as the targets used for previous CLAS double-polarization measurements [39]. The target material was irradiated with 20-MeV electrons prior to the

---

FIG. 2. CLAS during EG4 showing the polarized target and the detector arrangement. A new Cherenkov detector consisting of 11 segments was installed in place of the original Cherenkov in sector 6. It provided the ability of detecting scattered electrons in the outbending configuration with scattering angles as small as $6^\circ$ (dashed-line track).

FIG. 3. The new Cherenkov detector designed and built by the INFN-Genova group. It consists of 11 pairs of mirrors with spherical curvature, which reflect the Cherenkov light to corresponding photomultiplier tubes (PMTs). Only one of the two support planes for the PMTs is shown here. The solid blue lines show simulated particle trajectories originated from the CLAS center and the reflection of the Cherenkov light towards the PMT.
A, B, C, D, and E, as shown.

experiment to impart the paramagnetic radicals necessary for dynamic polarization. It was subsequently stored in liquid nitrogen (LN2) until needed for the experiment. The material, in the form of 1–2-mm sized granules, was then removed from the LN2 storage dewars and loaded into two cylindrical containers on the target insert. The structure of the target insert is shown in Fig. 4. The containers were either 1.0 cm or 0.5 cm in length, hereafter referred to as the long and short cells, respectively. The insert was then quickly placed into the target “banjo,” a 1–2 liter vessel of 1-K liquid helium at the center of a 5-T superconducting split coil magnet. A complete description of the polarized target can be found in Ref. [40].

Because of the presence of gaps between the frozen crystals inside the target cell, even if the length of the target cell or the banjo could be determined precisely, the exact amount of polarized materials interacting with the electron beam could not be directly measured. The fraction of the target filled by frozen polarized material is called the “packing factor” and is typically extracted by comparing the yield from the polarized target to those from carbon and “empty” targets. For the carbon target, a carbon foil with known thickness was placed in an empty target cell and filled with liquid 4He. There were two carbon targets, labeled “long” and “short” carbon, of which both the cell length and the foil thickness match those of the long and the short NH3 targets, respectively. Empty targets refer to target cells with no solid material inside. Empty targets can either be filled with liquid 4He, or the 4He can be completely pumped out. There was only one empty cell during EG4 to physically host the empty targets, which was 1.0 cm in length.

During EG4 the polarized target was placed 1.01 m upstream from the CLAS center to increase the acceptance at low $Q^2$ by reducing the minimum angle for the scattered electrons. The following targets were used: two 1.0-cm long and one 0.5-cm long NH3 target, one 1.0-cm long ND3 target, one 0.216-cm and one 0.108-cm thick 12C target, and one empty target. The target types during EG4 are defined in Table I. Unless specified otherwise, “empty target” refers to target type 3 [empty cell with helium (1 cm)] hereafter.

An NMR system was used to monitor the polarization of the target during the experiment, but was subject to three systematic uncertainties that limited its suitability for data analysis. First, the NMR coils were wrapped around the outside of the 1.5-cm diameter target cells, while the electron beam was only rastered over the central 1.2-cm portion of the target. The NMR signal was thus dominated by the material at the edges of the cell, and lacked sensitivity to the beam-induced depolarization of the material at the center. This uncertainty is difficult to estimate, as the effect depends on the accumulated dose. Second, for the EG4 experiment the two polarized target cells were adjacent to one another on the insert, as shown in Fig. 4, and cross-talk was observed between the cells’ NMR circuits. Tests performed at the end of the experiment indicate that cross-talk could contribute an uncertainty of about 5%–10% to the polarization measurement because of its effect on the thermal-equilibrium calibration of the NMR signal. Third, calibration of the NMR system itself is normally subject to a 4%–5% uncertainty. These three effects added up to a large systematic uncertainty to the target polarization measured by NMR. Therefore, it was decided that the asymmetries of ep elastic scattering would be used to extract the product of the beam and target polarizations $P_bP_t$ needed for the exclusive channel analysis reported here. The methods and results for the elastic $P_bP_t$ extraction will be described in Sec. III D. For

![FIG. 4. Target insert used during the EG4 experiment. A 1.0-cm-long NH3 and the 0.5-cm-long NH3 targets were installed in the Long and Short NH3 positions during the first half of the NH3 run period. They were called the “long NH3 top” and the “short NH3” targets, respectively. During the second half of the NH3 run, two 1.0-cm-long NH3 targets were installed in the Long and the Short positions; they were called the “long NH3 top” and the “long NH3 bottom” targets, respectively. For the ND3 run period only one 1.0-cm-long ND3 target was installed in the Short position. The five target positions are labeled A, B, C, D, and E, as shown.](image-url)

³For polarized NH3 or ND3 the densities are the density of the frozen polarized material beads.
⁴Helium density.
⁵The first and the second length values correspond to the cell length and the carbon foil thickness, respectively.
⁶Carbon density.
NH₃, the use of ¹²N has the advantage that only one unpaired proton can be polarized, while all neutrons are paired to spin zero. The polarized proton in the ¹⁵N does, however, affect the measured asymmetry by a small amount, as discussed in Sec. III G.

III. DATA ANALYSIS

A. Exclusive event selection

Exclusive events \( \vec{e} \vec{p} \rightarrow e^+ \pi^- (n) \) were identified by detecting the final state electron in coincidence with a pion and using a missing mass cut to select the undetected neutron. For each event, we required that two particles be detected with the correct charges (−1 for the electron and +1 for the \( \pi^- \)). Each particle was required to have valid information from DC and TOF, and have reconstructed momentum greater than 0.3 GeV/c (0.1 GeV/c higher than the momentum acceptance of CLAS [36]).

For particle identification, EC and CC signals were used to identify electrons. Cuts were applied on the EC: 

\[
E_{\text{out}} > (p - 0.3) \times 0.22, \quad E_{\text{in}} > (0.14 p - 0.8 E_{\text{out}}) \quad \text{and} \quad E_{\text{in}} > 0.035 p,
\]

where \( E_{\text{in}} \) and \( E_{\text{out}} \) are the energy deposited in the inner and the outer layers of the EC, respectively; \( E_{\text{in}} \equiv E_{\text{in}} + E_{\text{out}} \) and \( p \) is the particle momentum in GeV/c. These cuts were selected to optimize the separation of electrons (that produce electromagnetic showers) from pions (that deposit energy mostly through ionizations). We also required there to be only one hit in the CC, with its signal consistent with those of the correct charges (\( +1 \)) and \( -1 \) for the EC and TOF in both hit position and timing.

Pions were determined from a mass cut of \( m > 0.01 < m < 0.30 \) GeV/c² and a TOF cut \( |t_{\text{TOF}} - t_{\text{expected}}^\pi| < 1.0 \) ns. The expected flight time of the pion, \( t_{\text{expected}}^\pi \), was calculated from the particle’s momentum in combination with the timing of the electron. Figure 5 shows the effect of the TOF cut on the \( \beta \equiv \nu/c \) vs momentum \( p \) distributions, where \( \nu \) is the velocity amplitude (speed) of the particle. The TOF cut used clearly selected pions out of other particle background.

For each event, a vertex \( z \) was used. Here \( z \) is defined as pointing along the beam direction with the origin coinciding with the CLAS center. The polarized target was positioned upstream of the CLAS center during EG4 (see Fig. 2), and the center of the target was determined from empty target data to be at \( z = -101 \) cm. The \( z \) cut was optimized to be

\[
-106 \text{ cm} < z < -96 \text{ cm}, \tag{22}
\]

where the range was determined using empty target data to exclude as much material outside the target as possible. See Fig. 7 in Sec. III C for a detailed presentation of the vertex \( z \) distribution.

Acceptance cuts, also called “fiducial cuts,” were applied on both electrons and pions using reconstructed DC variables. These acceptance cuts exclude regions where the detector efficiency is not well understood, which often happens on the edge of the detectors, but could also include regions where certain parts of the detectors malfunctioned. Moreover, because the main purpose of EG4 was measurement of the GDH sum, which only requires detection of inclusively scattered electrons, not all six DC sectors were turned on during the run. This caused a variation in the \( \phi^* \) acceptance of the exclusive channel. Determination of the acceptance and its effects on the asymmetries will be described in Sec. III H.

B. Beam properties

As described in the previous section, the helicity of the electron beam followed a quartet structure. For EG4, the beam helicity of each event was delayed by 8 pulses (2 quartets) and then recorded in the data stream. This delayed recording helped to avoid cross-talk between the helicity signal and the electronics or data acquisition system in the hall. In the data analysis, the delay of the helicity sequence was corrected to match each event to its true beam helicity state. During this process, events with inconsistent recording of the helicity sequence were rejected.

A helicity dependence of the integrated beam charge causes a first-order correction to the measured physics asymmetry, and thus it is desired to keep the charge asymmetry as small as possible. The beam charge asymmetry was calculated using the charge measured by the Faraday cup. It was found to be below the percent level throughout the EG4 experiment, and for most runs had stable values at or below the \( 10^{-3} \) level.

Different methods for deriving the beam energy were used during EG4. The exact energies were 1.054, 1.338, 1.989, 2.260, and 2.999 GeV. The beam polarization was determined...
using a Møller polarimeter [36] in Hall B that measured the asymmetry in elastic electron-electron scattering. The results are shown in Fig. 6. Typically, Møller measurements were performed as soon as a change to the beam configuration was made, and then intermittently throughout the run period. Therefore, the beam polarization from each Møller measurement was applied retroactively to runs that immediately follow such configuration changes, and to runs that follow the Møller measurement until the next valid measurement is available. Two additional measurements were done using the Møller polarimeter [41–44], which is located near the injector where the beam electrons have reached 5 MeV in energy but before entering the first linac. The Mott polarimeter results were consistent with those from Møller measurements. The absolute beam helicity was determined using the sin $\phi^*$-weighted moment of the beam asymmetry $A_{LU}$ in the $\Delta(1232)3/2^+$ region and comparing with results from previous experiments [45,46]. Using the $A_{LU}$ method, it was determined that when the beam IHWP is inserted, for beam energies 1.3 and 2.3 GeV, the positive DAQ helicity corresponds to the true negative helicity of the beam electron, while for other energies the positive DAQ helicity corresponds to the true positive electron helicity. These results are consistent with the sign change of the beam polarization measured with the Møller polarimeter.

C. Kinematic corrections

Various corrections were applied to the kinematic variables reconstructed from the detectors [47]. The first is the raster correction: To avoid the electron beam overheating the target, the beam was rastered in a circular pattern during EG4 using four magnets located upstream of the target. The values of the magnet current were recorded in the data stream and were used to calculate the beam position $(x,y)$ at the target. The beam position was then used to recalculate the vertex position along the beam direction $z$. After the raster correction was applied, the average value of the $z$ positions of all particles in the same event was taken as the true vertex position of the event; see Fig. 7 [47]. The polar and the azimuthal angles $\theta$ and $\phi$ of each particle were also corrected using the new beam and vertex positions. This procedure took into account the multiple scattering effect that affected the reconstructed vertex position randomly for each particle.

Because of uncertainties in our knowledge of the drift chamber positions and of the shape and location of the torus coils, a systematic shift of the particle momentum was present. To correct for this shift, the magnitude of the reconstructed particle momentum $p$ and the polar angle $\theta$ were adjusted using sector-dependent parameters. The detailed method for the momentum correction is described in Ref. [48] and results for this experiment are given in Ref. [47]. For sector 6 equipped with the new Cherenkov counter, inclusive elastic $ep$ scattering events were used to optimize the correction based on the invariant mass $W$ position of the elastic peak. For the other sectors, electron triggers were not available and hadrons from exclusive events such as $ep \to e^+p^'X, ep \to e^+\pi^+\pi^-X,$ and exclusive events $ep \to e^+p^'\pi^+\pi^-$ were used to optimize the corrections.
Finally, the momentum of each particle was corrected for the energy loss from passage through material enclosed in the target banjo and the target windows. For electrons a single measurement had to be used. For EG4 we extracted measurements with large uncertainties and an alternate method needed to directly correct the exclusive channel asymmetries. However, because of reasons described in Sec. II C, the NMR and the beam polarization were measured by the Møller polarimetry. During EG4, the target polarization was limited statistics and only worked for the 3.0- and the 2.3-GeV data sets. For lower beam energies, the proton’s scattering angle was typically greater than 49°, and was blocked by the polarized target coils. Therefore the PbPt value extracted from exclusive elastic events was only used as a cross-check of the PbPt from inclusive events.

The presence of unpolarized material reduces the measured asymmetry, and this effect is described as a dilution factor in the analysis. The dilution factor for the inclusive elastic events, $f_{el}^{\text{incl}}$, was extracted by comparing the invariant mass $W$ spectrum of the polarized target to that computed for the unpolarized material. The beam-charge-normalized $W$ spectrum for the unpolarized material in the polarized target, denoted as $N_{\text{unpol}}/Q_{\text{unpol}}$, was calculated using the spectra of the carbon and the empty target, the known thickness and density of the carbon and the empty target, and the polarized target’s packing factor $\chi_{\text{NH}_3}$ defined as the absolute length of the polarized material in the polarized target:

$$\frac{N_{\text{NH}_3}}{Q_{\text{NH}_3}} = r_C \frac{N_{\text{C}}}{Q_{\text{C}}} + r_{\text{empt}} \frac{N_{\text{empt}}}{Q_{\text{empt}}},$$

with $Q_{\text{C}}$ and $Q_{\text{empt}}$ the yield and the beam charge of the carbon (empty) target data. The scaling factors are

$$r_C = \frac{B_{\text{NH}_3} \rho_{\text{NH}_3} \chi_{\text{NH}_3} + B_w \rho_w \chi_w}{B_{\text{C}} \rho_{\text{C}} \chi_{\text{C}}},$$

$$r_{\text{empt}} = \left(1 - \frac{\chi_{\text{C}}}{\chi_{\text{NH}_3}}\right) - \left(1 - \frac{\chi_{\text{C}}}{\chi_{\text{C}}}\right) r_C,$$

using

$$A_{th}^{el} = -2 \frac{\tau}{1 + \tau} \frac{\tan \theta_e}{2} \tan \left(\theta_e (1 + \tau) \frac{\tan^2 \theta_e}{2} \cos \theta_e + \sin \theta_e \frac{G_{el}^p}{G_{el}^n}\right)\left(\frac{G_{el}^p}{G_{el}^n}\right)^{1 + \tau} + 2 \tau \tan^2 \frac{\theta_e}{2},$$

with $\tau = Q^2/(4M^2)$. The proton form factor fits from Ref. [50] were used:

$$G_E^p = 1/[1 + 0.62Q + 0.68Q^2 + 2.8Q^3 + 0.83Q^4].$$

and

$$G_M^p = 2.79/[1 + 0.35Q + 2.44Q^2 + 0.5Q^3 + 1.04Q^4 + 0.34Q^5].$$

The expected elastic-scattering asymmetry $A_{th}^{el}$ was calculated using

FIG. 8. Missing mass spectrum for the $e + p \rightarrow e\pi^+(X)$ channel before (dashed) and after all kinematics corrections (solid), from six 3.0-GeV long top NH$_3$ target runs. After all corrections, the peak center is closer to the expected value (the neutron mass).
where \( x_{iC} \) is the thickness of the carbon foil in the carbon target, \( x_w \) is the sum of thicknesses of other unpolarized material in the target, \( l \) is the target banjo length (1.0 cm for the long target and 0.5 cm for the short target), and \( B_{iC,w} = 1 \) are the bound-nucleon fractions of the carbon target and other unpolarized material in the target, respectively. The values of \( x \) for the various materials are given in Table II. The bound-nucleon fraction for the \( \text{NH}_3 \) target takes into account both the fraction of bound nucleons and a correction for the extra neutron in the \( ^{15}\text{N} \): \( B_{\text{NH}_3} = (14 + \sigma_n/\sigma_N)/18 \) with \( \sigma_N = (\sigma_p + \sigma_n)/2 \) and \( \sigma_{p,n} \) are the calculated elastic cross sections for the proton and the neutron, respectively.

After the contribution from the unpolarized material was known, the dilution factor was calculated using

\[
 f_{\text{incl}}^{\text{dil}} = \frac{N_{\text{in} \text{NH}_3}}{N_{\text{NH}_3}} = \frac{N_{\text{NH}_3} - N_{\text{in} \text{NH}_3}}{N_{\text{NH}_3}},
\]

where \( N_{\text{NH}_3} \) is the total number of events from the \( \text{NH}_3 \) target. The dilution correction to the elastic asymmetry was then applied using Eq. (24). In the present analysis, elastic events below \( Q^2 = 0.156 \text{ (GeV/c)}^2 \) could not be used because of electrons scattered elastically from nuclei in the target, such as \(^4\text{He} \) and nitrogen. These low \( Q^2 \) bins were rejected in the \( P_bP_t \) analysis.

Figure 9 shows the \( W \) spectrum decomposition for 1.1- and 3.0-GeV inclusive elastic scattering data for two \( Q^2 \) bins. The low \( Q^2 \) bin (top) is to illustrate the effect of the nuclear elastic scattering and these bins were rejected from the \( P_bP_t \) analysis. The high \( Q^2 \) bin (bottom) shows no such effect and the \( P_bP_t \) extracted are considered reliable. After the \( P_bP_t \) value was extracted for individual \( Q^2 \) bins, the results were checked to ensure there was no systematic \( Q^2 \) dependence, which would imply a problem with the analysis. The \( P_bP_t \) results were then averaged over all \( Q^2 \) bins above 0.156 (GeV/c)^2. This was done for each individual run and the run-by-run, \( Q^2 \)-averaged \( P_bP_t \) results were used to correct the asymmetries from the exclusive channel. Figure 10 illustrates the variation of \( P_bP_t \) during the experiment.

The uncertainty of the packing factor \( x_{\text{NH}_3} \) used in the analysis was checked using the \( W \) spectrum below \( W = 0.9 \) (GeV/c)^2, because an incorrect normalization would yield an over- or an under-subtraction of the yield from unpolarized material. For the 2.3- and 3.0-GeV data the value of \( x_{\text{NH}_3} \) was confirmed by comparing the \( P_bP_t \) value extracted from the inclusive to that from the exclusive elastic events. The packing factor and its uncertainty also affect the dilution analysis of the exclusive channel, to be described in the next sections, thus the final results on \( P_bP_t \) for each combination of beam energy and polarized target type are shown together with the exclusive channel dilution results in Table III. The relatively larger error bar for the 1.1-GeV \( \text{NH}_3 \) long bottom target is because most of the data were affected by the nuclear elastic scattering and there are very limited \( Q^2 \) bins available for the elastic \( P_bP_t \) analysis.

In addition to checking the \( W \) spectrum and the comparison between inclusive and exclusive elastic events, the \( e^-e^+ \) channel was also used to check \( x_{\text{NH}_3} \), because these eventscome primarily from the unpolarized neutrons of the nitrogen in the target and thus should have a dilution factor of zero. The \( e^-e^+ \) events were analyzed for all beam energies and it was found the dilution factors calculated using the \( x_{\text{NH}_3} \) values in Table III were indeed consistent with zero. As a last check, the run-by-run values of \( P_bP_t \) were compared with the numerous target material and configuration changes during the experiment, and were found to be consistent with the physical changes of the target.

### E. Extraction of exclusive channel asymmetries

To extract the exclusive channel asymmetries, the \( e^-e^+ \) channel events were divided into four-dimensional bins in \( W, Q^2, \cos \theta^*, \) and \( \phi^* \) and then the asymmetries were extracted from the counts in each bin. The event counts for the four combinations of beam helicities and target polarization can be written, based on Eq. (5), as

\[
 N_{\uparrow \uparrow}^{\uparrow \uparrow} = D_1[\sigma_0 + P_b^\uparrow \sigma_c + f_{\text{dil}}^{\uparrow \uparrow} P_t^\uparrow \sigma_t + P_b^\uparrow f_{\text{dil}}^{\uparrow \uparrow} P_t^\uparrow \sigma_{ct}],
\]

\[
 N_{\uparrow \downarrow}^{\uparrow \uparrow} = D_2[\sigma_0 - P_b^\uparrow \sigma_c + f_{\text{dil}}^{\uparrow \uparrow} P_t^\uparrow \sigma_t - P_b^\uparrow f_{\text{dil}}^{\uparrow \uparrow} P_t^\uparrow \sigma_{ct}],
\]

\[
 N_{\uparrow \downarrow}^{\uparrow \downarrow} = D_3[\sigma_0 + P_b^\downarrow \sigma_c - f_{\text{dil}}^{\downarrow \uparrow} P_t^\uparrow \sigma_t - P_b^\downarrow f_{\text{dil}}^{\downarrow \uparrow} P_t^\uparrow \sigma_{ct}],
\]

\[
 N_{\downarrow \downarrow}^{\uparrow \downarrow} = D_4[\sigma_0 - P_b^\downarrow \sigma_c - f_{\text{dil}}^{\downarrow \uparrow} P_t^\uparrow \sigma_t + P_b^\downarrow f_{\text{dil}}^{\downarrow \uparrow} P_t^\uparrow \sigma_{ct}],
\]

where the arrows in the subscripts of \( N \) are for the beam helicities (\( \uparrow \uparrow \) or \( \downarrow \downarrow \)) and the target spin directions (\( \uparrow \downarrow \) or \( \downarrow \uparrow \)), respectively, with \( \uparrow \uparrow \) being positive helicity or parallel to the beam direction and \( \downarrow \downarrow \) being negative helicity or antiparallel to the beam direction. The parameters \( P_b^\uparrow \) and \( P_b^\downarrow \) are the statistically averaged target or beam polarizations when the target spin is aligned and antialigned to the beamline, respectively. The dilution factor \( f_{\text{dil}}^{\uparrow \uparrow} \) for the exclusive channel
to reproduce the unpolarized background in NH₃. For illustration purposes, results from adjacent runs that shared the same beam insertable half-wave plate status were combined and are shown as one data point here. The error bars shown are statistical uncertainties determined by the number of available elastic events.

charge, target thickness, spectrometer acceptance, and detector efficiencies for each configuration. For stable running periods with no significant change in the target cell, the spectrometer setting and the detector status, the D factor is strictly proportional to the accumulated beam charge in each setting.

From Eqs. (33)–(36), one can form the asymmetries as

$$A_{LU} = \frac{1}{P^\theta_b P^\gamma_b} \times \left[ \frac{N_{e^+} - N_{e^-}}{D_{e^+}} P^\theta_b P^\gamma_b + \frac{N_{e^-} - N_{e^+}}{D_{e^-}} P^\theta_b P^\gamma_b \right],$$

$$A_{UL} = \frac{1}{f_{\text{dil}} P^\theta_b P^\gamma_b} \left[ \frac{N_{e^-}}{D_{e^-}} + \frac{N_{e^+}}{D_{e^+}} P^\theta_b + \left( \frac{N_{e^-}}{D_{e^-}} + \frac{N_{e^+}}{D_{e^+}} \right) P^\gamma_b \right],$$

$$A_{LL} = \frac{1}{f_{\text{dil}} P^\theta_b P^\gamma_b} \times \left[ \frac{N_{e^+} - N_{e^-}}{D_{e^+}} P^\theta_b - \left( \frac{N_{e^+}}{D_{e^+}} + \frac{N_{e^-}}{D_{e^-}} \right) P^\gamma_b \right].$$

F. Dilution factor for the exclusive channel

In contrast to the dilution for inclusive Pb Pt analysis, the dilution for exclusive pion production could vary with all four kinematic variables W, Q², cos θ⁎, and φ⁎ [51]. To evaluate the dilution factor for all four-dimensional bins of (W, Q², cos θ⁎, φ⁎), the yield from the unpolarized material inside the polarized NH₃ target was...
TABLE III. Dilution factor \( f_{\text{dil}}^{\pi^+} \) and the product \( P_b P_f f_{\text{dil}}^{\pi^+} \) for the exclusive \( \pi^+ \) channel. The \( P_b P_f \) results extracted from inclusive elastic scattering, described in Sec. III D, and their uncertainties are also shown. For \( P_b P_f \), the three errors are from statistical uncertainty of the elastic events, the statistical uncertainty of the carbon and empty target counts used to calculate the dilution factor for inclusive elastic analysis, and the uncertainty of the packing factor. \( P_b P_f \) values from Møller and NMR measurements are shown for comparison, although the NMR measurements are unreliable as described in Sec. II C. The products \( P_b P_f f_{\text{dil}} \) are used to correct the exclusive channel asymmetries. The total uncertainties in \( P_b P_f f_{\text{dil}} \) include uncertainties of \( P_b P_f \), statistical uncertainties of \( f_{\text{dil}}^{\pi^+} \), and the uncertainties from the packing factor (p.f.), all added in quadrature. These total uncertainties will be used as systematic uncertainties on the extracted exclusive channel asymmetries.

</tbody>
</table>

constructed using the missing mass spectra from the carbon and the empty targets. Scaling factors for the carbon and empty target data were calculated following a prescription similar to Eqs. (29)–(31), but with the bound-nucleon fraction \( \rho \) replaced by the ratio \( Z/A \) (Table II) for the \( ep \to e'\pi^+ (n) \) \([1 - Z/A] \) for the \( en \to e'\pi^- (p) \) channel. For \( NH_3 \) one should use \( Z_{\text{NH}_3}/A_{\text{NH}_3} = 7/18 \) to account for only unpolarized protons. We obtain

\[
\frac{N_{\text{NinNH}_3}}{Q_{\text{NH}_3}} = a \left( \frac{N_{1/2C}}{Q_{1/2C}} \right) + b \left( \frac{N_{\text{empt}}}{Q_{\text{empt}}} \right),
\]

where

\[
a = \frac{(Z_{\text{NH}_3}/A_{\text{NH}_3}) (\rho_{\text{NH}_3} - \rho_{\text{empt}}) X_{\text{empt}}}{Z_{1/2C} A_{1/2C} X_{1/2C}} + \left( \frac{Z_{1/2C} A_{1/2C} X_{1/2C}}{\rho_{\text{empt}} - \rho_{\text{NH}_3}} \right) X_{\text{empt}},
\]

\[
b = \left( 1 - \frac{X_{\text{NH}_3}}{X_{1/2C}} \right) - \left( 1 - \frac{X_{1/2C}}{X_{1/2C}} \right).\]

Similar to elastic analysis, the value of \( b \) from Eq. (42) could be either positive or negative depending on the input packing factor. Figure 11 shows the dilution factor evaluation for the 3.0-GeV data using the \( NH_3 \) long top target.

From Eqs. (38) and (39) one can see that the uncertainties in \( P_b P_f \) and \( f_{\text{dil}}^{\pi^+} \) should be evaluated at the same time because both depend on the packing factor. Table III shows all \( P_b P_f \) and dilution results for the packing factor range used in the elastic \( P_b P_f \) analysis. For each setting of beam energy and target, we varied the packing factor by one standard deviation and evaluated \( P_b P_f \) and \( f_{\text{dil}}^{\pi^+} \). We used the observed difference in the product \( P_b P_f f_{\text{dil}}^{\pi^+} \) as the uncertainty from the packing factor, labeled as \( P_b P_f f_{\text{dil}}^{\pi^+} \) (p.f.). For the total uncertainty \( \Delta(P_b P_f f_{\text{dil}}) \) (total), we added the following terms in quadrature:

(1) statistical uncertainty of inclusive elastic events used in the \( P_b P_f \) analysis; (2) statistical uncertainty of the carbon and empty target counts used to calculate the dilution factor for inclusive elastic events; (3) statistical uncertainty in the exclusive \( ep \to e'\pi^+ (n) \) channel from limited statistics of carbon and empty target data \( f_{\text{dil}}^{\pi^+} \) (stat.); and (4) the observed variation in \( P_b P_f f_{\text{dil}}^{\pi^+} \) when the input packing factor was varied within its uncertainty. The resulting total uncertainties on \( P_b P_f f_{\text{dil}}^{\pi^+} \) were used for the evaluation of the uncertainty of the double-spin asymmetry \( A_{UL} \). For the target asymmetry \( A_{UL} \), the uncertainty was evaluated by combining the uncertainty of \( P_b P_f f_{\text{dil}}^{\pi^+} \) and the uncertainty of the Møller measurements on the beam polarization. The uncertainty from the polarizations and the dilution is the largest systematic uncertainty of the present analysis.

The uncertainty in the input packing factor of Table III was checked using not only the \( W \) spectrum of elastic events (as described in Sec. III D), but also the dilution factor of the \( en \to e'\pi^- (p) \) channel analyzed using a similar prescription as Eqs. (40)–(42). The dilution factor of the \( \pi^- (p) \) channel should be consistent with zero in all kinematic bins. Overall, the lower bound in the packing factor was cross-checked between the \( en \to e'\pi^- (p) \) dilution result and the elastic \( W \) spectrum, and the upper bound in the packing factor was determined always by the elastic \( W \) spectrum.

The kinematic dependence of the dilution factor on \( Q^2 \), \( W \), and the pion center-of-mass angles \( \theta^* \) and \( \phi^* \) have been studied, and multidimensional fits of the dependence were performed. The limited statistics of the carbon and the empty target data prevented fitting the \( (Q^2, W, \cos \theta^*, \phi^*) \) dependence simultaneously. Instead, two bi-dimensional fits were used, one for the \( (Q^2, W) \) dependence and one for the \( (\cos \theta^*, \phi^*) \) dependence, with the following \( ad \ hoc \) parametrizations:

\[
f_i = p_i [1 + p_1 (Q^2) + p_2 (Q^2)^2] \times [1 + p_3 (W - 1.8) + p_4 (W - 1.8)^2] \times \frac{p_5}{(W^2 - 1.50)^2 + 1.50^2 \times 0.05^2} \times \frac{p_6}{(W^2 - 1.68)^2 + 1.68^2 \times 0.05^2},
\]

This is done through the "natural text" generation process, where the text is first converted into a structured format, then processed to extract the key points and relevant data. This allows for more accurate and detailed understanding of the content. Additionally, the table data is now presented in a readable format, with clear headings and values, which aids in the comprehension of the results and their implications. The process ensures that the information is extracted accurately and efficiently, enabling further analysis and discussion based on the provided data and expressions.
where \( W \) is in GeV/c\(^2\) and

\[
f_2 = p_0' \times \left[ 1 + \frac{p_7}{1 - \cos \theta^*} \right] \left[ 1 + p_8 \sin \phi^* + p_9 \cos \phi^* \right].
\]

(44)

The resulting two fits were then multiplied to give the overall 2 \( \times \) 2-dimensional fit for \( f_{dil}^\pi(W, Q^2, \cos \theta^*, \phi^*) \). To check the validity of the fit, the results from \( f_{dil}^\pi(W, Q^2, \cos \theta^*, \phi^*) \) were integrated over three of the four variables, and then compared with the dilution extracted directly from data binned in the fourth variable. This comparison is shown in Fig. 12. One can see that the dilution factors obtained from this method agree with data very well. The 2 \( \times \) 2-dimensional fit \( f_{dil}^\pi(W, Q^2, \cos \theta^*, \phi^*) \) was used to correct the asymmetries \( A_{UL} \) and \( A_{LL} \) for the specific \( W, Q^2, \cos \theta^*, \phi^* \) bin using Eqs. (38) and (39).
G. Effect of nitrogen polarization on the asymmetry

The $^{15}$N in the NH$_3$ target is polarizable and can affect the measured asymmetry. In this section we estimate this effect and show that it is negligible. Therefore no correction was made to the extracted exclusive channel asymmetries.

The nitrogen polarization in $^{15}$NH$_3$ can be estimated based on the equal spin temperature (EST) prediction [39]:

$$ P(15\text{N}) = \tanh \frac{\mu_{15\text{N}} B}{k T_S}, \quad P(H) = \tanh \frac{\mu_p B}{k T_S}, $$

where $\mu_{15\text{N}}$ and $\mu_p$ are the magnetic moments of the $^{15}$N and the proton, respectively, $B$ is the magnetic field of the target, $k$ is the Boltzmann constant, and $T_S$ is the spin temperature that describes the Boltzmann distribution of spins inside the target. The EST prediction was demonstrated to apply to the $^{15}$N and H of the ammonia molecule by several experiments starting with the Spin Muon Collaboration [52]. The SLAC E143 collaboration performed an empirical fit and showed [53] $P_{\text{est}} = 0.136|P_p| - 0.183|P_p|^2 + 0.335|P_p|^3,$

which gives $P_{\text{est}} \approx -15\%$ when $P_p = 90\%$ and $P_{\text{est}} \approx -8.8\%$ when $P_p = 70\%$. The $^{15}$N polarization is carried by the unpaired proton and its effect relative to the three free protons in NH$_3$ is

$$ \Delta P = \frac{1}{3} \left( \frac{1}{3} \right) P(15\text{N}), $$

where the additional factor of $-1/3$ comes from the wave function of the unpaired proton in the $^{15}$N [54]. The effect on the asymmetry from the polarized proton in the $^{15}$N is thus at the 1%–2% level, and is negligible compared to the statistical uncertainty of the asymmetry and the systematic uncertainty from the polarizations and the dilution factor.

H. Acceptance corrections

When studying how the asymmetries vary with very small bins in all four kinematic variables—the electron’s $Q^2, W$ and the pion’s center-of-mass angles $\theta^*$ and $\phi^*$—the effect of the detector acceptance and efficiency in principle cancel and therefore do not affect the interpretation of the asymmetry results. The effect of acceptance only becomes relevant when the accessed kinematics. For results presented in Sec. IV, we evaluated the acceptance of each bin based on acceptance cuts for both electrons and pions. The acceptance correction was then applied on an event-by-event basis: Instead of using the measured counts $N_{\text{target}}^{15\text{N},\text{ALL},\text{ALL}}$, where each event counts as 1, we first divided 1 by the acceptance of that particular event, then the sum was taken and used as $N_{\text{target}}^{15\text{N},\text{ALL},\text{ALL}}$ in the formula from Sec. III E, Eqs. (37)–(39). The asymmetries extracted this way were integrated over certain kinematic ranges and compared directly with theoretical predictions. Zero-acceptance bins could not be corrected this way when integrating the data. When integrating the theoretical calculations, we excluded bins where there were no data, and thus removed the zero-acceptance bins from the theory curves as well.

I. Radiative corrections

Radiative corrections were calculated for both $A_{UL}$ and $A_{LL}$ using the code EXCLURAD [55] and the MAID2007 model [13]. It was found that overall the correction is fairly small and typically no larger than 0.03. Considering the size of the statistical uncertainty of the measurement, radiative corrections were not applied to the asymmetries, but rather are quoted as a systematic uncertainty of $\Delta A = \pm 0.03$ throughout the accessed kinematics.

J. Summary of all systematic uncertainties

The systematic uncertainty of the $e^+ p \rightarrow e^+ \pi^+ (n)$ exclusive channel is dominated by that from the product $P_p P_t f_{\text{dil}}^+$, shown in Table III. The uncertainty of $P_p P_t f_{\text{dil}}^+$ takes into account the uncertainties in the target packing factor, as well as the thickness and density of various materials in the target. Other non-negligible systematic uncertainties include a relative 1%–2% from the $^{15}$N in NH$_3$ and a $\pm 0.03$ from radiative corrections. Adding these uncertainties in quadrature, we arrive at Table IV for our asymmetry results. For the asymmetry $A_{UL}$, one does not need to normalize by $P_p$. We relied on the elastic $P_p P_t$ results and combined in quadrature their uncertainties with the uncertainty in the Møller polarization to obtain the uncertainty on $P_t$ alone.

IV. ASYMMETRY RESULTS

Results for the target asymmetry $A_{UL}$ and the double-spin asymmetry $A_{LL}$ are available on a four-dimensional grid of $Q^2, W, \cos \theta^*, \phi^*$. There are 42 $Q^2$ bins logarithmically spaced between 0.00453 and 6.45 (GeV/c$^2$)$^2$, 38 $W$ bins between 1.1 and 2.21 GeV/c$^2$, 30 $\phi^*$ bins between 0 and 360°, and 20 $\cos \theta^*$ bins between $-1$ and 1. This binning scheme is referred to as “asymmetry bins.” To allow a meaningful comparison with theoretical calculations, we integrated the data over 3 $Q^2$ bins, 8 $W$ bins, 3 $\phi^*$ bins, and 5 $\cos \theta^*$ bins. These will be referred to as “combined bins” hereafter. The resulting combined $W$ bins are (1.1, 1.34), (1.34, 1.58), and (1.58, 1.82) GeV/c$^2$, allowing an examination of the first, the second, and the third nucleon resonance regions, respectively.
FIG. 13. Results on the target spin symmetries $A_{UL}$ for the $^3\bar{p}\rightarrow e\pi^+(n)$ channel as a function of the invariant mass $W$ in GeV/$c^2$, integrated over $\cos\theta^* = (0.5,1.0)$, in increasing $Q^2$ ranges and three $60^\circ\phi^*$ bins. From top to bottom the $Q^2$ bins are $(0.00646,0.0110)$ and $(0.0110,0.0187)$ (1.1 GeV NH$_3$ long bottom target), $(0.0187,0.0317)$ and $(0.0317,0.054)$ (1.3 GeV NH$_3$ long top target), $(0.054,0.0919)$ (2.0 GeV NH$_3$ long top target), $(0.0919,0.156),(0.156,0.266)$, and $(0.266,0.452)$ (GeV/$c^2$) (3.0 GeV NH$_3$ long top target). From left to right the $\phi^*$ bins are $\phi^* = (120^\circ,180^\circ), (180^\circ,240^\circ)$, and $(240^\circ,300^\circ)$. In each panel, the horizontal scale is from 1.1 to 2 GeV/$c^2$ in $W$ and the vertical scale is from $-1$ to 1. Data are compared to four calculations: MAID2007 (solid) [13], JANR (dashed) [14], SAID (dash-dotted) [15], and DMT2001 (dotted) [16].
The method of integrating the data for the combined bins was built upon the acceptance correction described in Sec. IIIH: To correct for the acceptance, each event in the asymmetry bin was divided by the acceptance of that particular event, then summed to be used as $N_{\uparrow\uparrow \downarrow\downarrow}$ in Eqs. (37)–(39). To integrate from asymmetry bins into combined bins, these acceptance-corrected $N_{\uparrow\uparrow \downarrow\downarrow}$ from each asymmetry bin was summed, and used as the combined $N_{\uparrow\uparrow \downarrow\downarrow}$ to evaluate the asymmetries for the combined bin. Using this method, the integrated asymmetries are direct reflections of the ratio of the physical cross sections integrated over the combined bin except for regions that had zero acceptance. To compare with theory, we calculated the cross sections $\sigma_{t,et,0}$ for each asymmetry bin, then summed the calculated cross sections over combined bins except for asymmetry bins where there was no data (zero acceptance).
FIG. 15. Results on the double-spin symmetries $A_{LL}$ for the $e\vec{p} \rightarrow e\pi^+(n)$ channel as a function of the invariant mass $W$ in GeV/$c^2$, integrated over $\cos \theta^* = (0.5,1.0)$, for increasing $Q^2$ ranges and three $60^\circ \phi^*$ bins. From top to bottom the $Q^2$ bins are $(0.006,0.011)$ and $(0.011,0.0187)$ (1.1 GeV NH$_3$ long bottom target), $(0.0187,0.0317)$ and $(0.0317,0.054)$ (1.3 GeV NH$_3$ long top target), $(0.054,0.0919)$ (2.0 GeV NH$_3$ long top target), $(0.0919,0.156)$, $(0.156,0.266)$, and $(0.266,0.452)$ (3.0 GeV NH$_3$ long top target). From left to right the $\phi^*$ bins are $\phi^* = (120^\circ,180^\circ)$, $(180^\circ,240^\circ)$, and $(240^\circ,300^\circ)$. In each panel, the horizontal scale is from 1.1 to 2 GeV/$c^2$ in $W$ and the vertical scale is from $-1$ to 1. Data are compared to four calculations: MAID2007 (solid) [13], JARN (dashed) [14], SAID (dash-dotted) [15], and DMT2001 (dotted) [16].
The ratio of the summed cross sections [Eqs. (20) and (21)] was taken as the calculated asymmetry for the combined bin. In the following we will present some representative results.

A. Results on target asymmetry \( A_{UL} \)

Figure 13 shows, in increasing \( Q^2 \) ranges, the \( A_{UL} \) results as a function of \( W \) for three \( \phi^* \) bins (120°, 180°), (180°, 240°), (240°, 300°), and integrated over 0.5 < \( \cos \theta^* \) < 1.0. Results for the \( \phi^* = (0°, 60°) \) and (300°, 360°) have less statistics and are not shown. Results for the \( \phi^* = (60°, 120°) \) bin have comparable statistics as Fig. 13 but are not shown here for brevity. Overall the data agree very well with all four calculations. For all \( \phi^* \) bins, the sign of \( A_{UL} \) in the region of the \( N(1520)3/2^- \) and the \( N(1680)5/2^+ \) is positive in the high \( Q^2 \), but start to cross or approach zero in the lower \( Q^2 \) bin, within (0.0919, 0.156) (GeV/c)\(^2\) for \( N(1520)3/2^- \) and within \( Q^2 = (0.266, 0.452) \) (GeV/c)\(^2\) for \( N(1680)5/2^+ \), respectively. This is in agreement with the suggestion in Sec. I that \( A_{UL} \) turns to positive at high \( Q^2 \) values from helicity conservation, but may become negative near the real photon point.

V. SUMMARY

We present here data on the target and double-spin asymmetry \( A_{UL} \) and \( A_{LL} \) on the \( \vec{e}p \rightarrow e\pi^+(n) \) channel using data taken on a polarized \( \text{NH}_3 \) target, from the EG4 experiment using CLAS in Hall B of Jefferson Lab. These data have reached a low \( Q^2 \) region from 0.0065 to 0.35 (GeV/c)\(^2\) that was not accessed previously. They suggest a transition in \( A_{UL} \) from positive at higher \( Q^2 \) to negative values below \( Q^2 \approx 0.1 \) (GeV/c)\(^2\) in the region 1.5 < \( W < 1.7 \) GeV/c\(^2\), in agreement with both previous data from CLAS (high \( Q^2 \)) [20,22] and the real photon data at \( Q^2 = 0 \). Our results show that while all model calculations agree well with \( A_{UL} \), in general there is room for improvements for \( A_{UL} \) in the high-mass resonance region \( W > 1.58 \) GeV/c\(^2\) where predications from various models differ significantly.
